Abstract – The Radio frequency Interference Survey of Earth (RISE) is a new type of instrument used to survey and characterize the presence of Radio Frequency Interference (RFI) that can affect microwave radiometers. It consists of a combined microwave radiometer and kurtosis spectrometer with broad frequency coverage and high temporal and spectral resolution. A K-Band airborne version has been built and flown across southeast Michigan. A kurtosis detector is included in RISE to reliably detect the presence of RFI, even at very low levels, and to aid in its characterization. A radiometer is included to measure the impact of the RFI on observed brightness temperature.

Keywords-microwave radiometer, radio frequency interference

I. INTRODUCTION

Evidence of RFI has been identified at C-band and at X-band by the Advanced Microwave Scanning Radiometer (AMSR-E) ((e.g. Li et al., 2004) as well as WindSat. Additionally, AMSR-E has shown that K-band measurements are susceptible to RFI which are believed to be generated by both ground-based sources as well as the reflection by the earth's surface of signals from geostationary telecommunication satellites (e.g. Li et al., 2004; Li et al., 2006). In particular, observed RFI centered at 18.7 GHz by AMSR-E and WindSat has significantly increased in 2008-2009 from 2005-2006 measurements. The RISE aircraft mission, operating over 18.7-19.3 GHz, will evaluate the K-band RFI environment in order to assess the optimal passband.

Section II will present an overview of the RISE radiometer hardware, followed by a description of the

execution of the RISE flight campaign in Section III. A discussion of the RISE measurements and analysis will follow in Section IV. Finally, conclusions regarding the K-Band RFI environment over south-east Michigan will be discussed.

II. INSTRUMENT DESCRIPTION

The RISE spectrometer, built in collaboration with the Danish Technical University, is a total-power radiometer with a stepped local oscillator (LO) and a digital back-end. A block diagram of the spectrometer is shown in Fig. 1. The spectrometer operates from 18.7 to 19.3 GHz with a spectral resolution of 3.28MHz and a 200 ms integration time. The initial signal is fed to the radiometer through a horn antenna followed by the calibration switch, which alternates from the antenna to the warm load or the cold FET. The warm and cold loads track the stability of the radiometer and serve as calibration points for the raw second moment antenna counts. The horn antenna has a beamwidth of 20° giving it a spatial resolution of approximately 1 km at an altitude of 8500 ft (typical altitude for RISE flight).

There are 16 stepped LO frequencies covering 18.7-19.3 GHz. The sequencing of radiometer measurement is shown in Fig. 2. The calibration switches to the cold FET, stepping through all 16 LO frequencies and then switches to sampling through the antenna the same way. It then repeats this process by switching from the antenna to the warm load and then switching back to the antenna, stepping through all LO frequencies. The RISE digital back-end consists of a X bit Y Gsamples/sample ADC followed by a Xilinx Z FPGA clocked at A MHz. Digital subbanding occurs in the FPGA over 16 subbands. The FGPA measures higher order moments including the second moment which is proportional to power, and the

Water crossings over Lake St. Clair and Lake Huron were used for brightness temperature (TB) calibration. Additional landmarks were selected for their diversity in surface topography. An RFI beacon was also installed above the Space Physics Research Building at the University of Michigan. It generated a continuous wave signal corresponding to a brightness temperature (TB) of XX at 19.0 GHz as observed by RISE.

IV. DATA ANALYSIS

Water crossings during the flight were noted to verify the geolocation of the antenna footprint. As seen in Fig. 4, the water crossings, corresponding to the raster scans made over the western coast of Lake Huron, are sharply defined as a marked decrease in 2nd moment counts. Calibration of antenna temperatures was accomplished using the internal hot and cold loads as well as the water

crossings assuming a linear relationship between raw radiometer second moment counts and TB. For freshwater at a temperature of 8.3 C, the expected V-Pol brightness temperature at 19.0 GHz (V-pol) would be 163.2 K (e.g. Klein et al., 1977). These antenna temperatures were converted to main beam TBs assuming a mainbeam efficiency of 83% and a side-lobe effective radiating temperature of X.

RFI was observed over the Ann Arbor airport, the RFI beacon, Flint, MI and at lower levels over the western coast of Lake Huron. The Ann Arbor airport shows the highest range of pulsed RFI (Figure 6a) where kurtosis is above 3 in the first two minutes of the flight. The beacon clearly shows the CW generated signal, where the kurtosis is below 3 as also seen in Figure 6a. Over different LO frequencies, the kurtosis varies as seen in Figure 6b and 6c.

V. CONCLUSIONS

The Radio frequency Interference Survey of Earth (RISE) is a new type of surveying tool that has identified RFI in the K-band. Future work for this survey will be critical in characterizing RFI generated from the reflection of geostationary satellites as well as identifying additional ground-based sources. The digitally filtered subbands will aid in future analysis in isolating specific frequencies where RFI occurs.
