Abstract

Prediction of solar storms has become a very important issue due to the fact that they can affect dramatically the telecommunication and electrical power systems at the earth. As a result, a lot of research is being done in this direction, space weather forecast. Magnetohydrodynamics systems are being studied in order to analyse the space plasma dynamics, and techniques which have been broadly used in the prediction of earth environmental variables like the Kalman filter (KF), the ensemble Kalman filter (EnKF), the extended Kalman filter (EKF), etc., are being studied and adapted to this new framework. The assimilation of a wide range of space environment data into first-principles-based global numerical models will improve our understanding of the physics of the geospace environment and the forecasting of its behaviour. Therefore, the aim of this paper is to study the performance of nonlinear observers in magnetohydrodynamics systems, namely, the EnKF.

The EnKF is based on a Monte Carlo simulation approach for propagation of process and measurement errors. In this paper, the EnKF for a nonlinear two-dimensional magnetohydrodynamic (2D-MHD) system is considered. For its implementation, two software packages are merged, namely, the Versatile Advection Code (VAC) written in Fortran and Matlab of Mathworks. The 2D-MHD is simulated with the VAC code while the EnKF is computed in Matlab. In order to study the performance of the EnKF in MHD systems, different number of measurement points as well as ensemble members are set.

1. Introduction

In this paper, a first attempt is done for investigating the performance of the ensemble Kalman filter (EnKF) [5,6] in space weather forecast. Space weather forecast is an area of research that has become very active in the last years due to the need to predict solar storms. These solar storms can dramatically affect the telecommunication, electrical power systems, satellites, pipelines, climate, etc., at the earth. To predict such events data assimilation techniques can be used, data assimilation consists basically of combining physical first-principle-based models with measurements of the physical variables. Hence, these measurements are used to correct the estimation of the dynamics of the whole system, due to the lack of information about initial conditions, boundary conditions, wrong and nonmodelled dynamics, etc. Therefore, in this paper we use magnetohydrodynamic (MHD) equations as basis for the physical first-principle-based model, and the EnKF for correcting the estimation of the physical variables.

One of the motivation for using the EnKF is that it is very easy to implement due to the fact that it does not need any model linearization like the extended Kalman filter (EKF) [1]. Therefore, the EnKF can be set mainly into two modules; the model simulator and the data assimilation module. These facts make the EnKF very attractive for real applications. Hence, in this paper we use the VAC code [11] as the MHD simulator module and Matlab for the data assimilation module. Finally, the two codes are run simultaneously using a script written in Matlab.

This paper is organized as follows, in Sections 2–4 the MHD system and EnKF are introduced, respectively. In Section 5 numerical results are presented and, finally, in Section 6 some conclusions are given.

2. MHD system equations

The topic of MHD is ubiquitous in plasma physics. Examples where the theory has been used with success range from explaining the dynamo generation and subsequent evolution of magnetic fields within stellar and planetary interiors, to accounting for the gross stability of magnetically confined thermonuclear plasmas. It transpires that MHD is capable of providing a good description of such large-scale disturbances, indicating that the MHD account of plasma behaviour is necessarily a macroscopic one. In essence, MHD is a macroscopic, nonrelativistic theory that is concerned with global phenomena in magnetic plasmas. It gives an accurate description of many of the complicated interactions of magnetic fields with the plasmas of the sun and stars. The theory is a marriage between fluid mechanics and electromagnetism. Despite its apparent simplicity, MHD describes a remarkably rich and varied mix of phenomena and the subject is one whose development continues to flourish [4,7].

The basic equations of MHD can be summarized as follows:

mass continuity:

\[
\frac{\partial \rho}{\partial t} + \nabla (\rho \mathbf{u}) = 0, \tag{1}
\]

adiabatic equation of state:

\[
\frac{d}{dt} \left( \frac{p}{\rho^\gamma} \right) = 0, \tag{2}
\]
momentum equation,

$$\rho \frac{d\mathbf{u}}{dt} = J \times \mathbf{B} - \nabla p,$$

(Ampere's law):

$$\nabla \times \mathbf{B} = \mu_0 \mathbf{J},$$

(Faraday's law):

$$\nabla \times \mathbf{E} = -\frac{\partial \mathbf{B}}{\partial t},$$

(Gauss' law):

$$\nabla \mathbf{B} = 0,$$

(resistive Ohm's law):

$$\mathbf{E} + \mathbf{v} \times \mathbf{B} = \eta \mathbf{J},$$

where each of the symbols has its customary meaning (see the list of symbols below), with the convective derivative

$$\frac{d}{dt} \triangleq \frac{\partial}{\partial t} + \mathbf{v} \nabla.$$

On the other hand, the right-hand side of (7) may be neglected to yield the ideal Ohm's law:

$$\mathbf{E} + \mathbf{v} \times \mathbf{B} = 0.$$

This states that there is no electric field in the rest frame of the fluid. Eqs. (1)–(6) with (8) constitute the ideal MHD equations, which is usually contracted to MHD. The inclusion of (7) is described as resistive MHD.

It can be seen that the equations are essentially an amalgam of fluids mechanics and 'pre-Maxwell' electromagnetism. The fluid inertia is affected by forces due to the fluid pressure gradients and to the \( J \times B \) term, which is the Lorentz force in continuum form. It will be noted, however, that the Ohm's law couples the fluid to the fields. If the magnetic flux is conserved, then this equation provides constraints on the allowable class of fluid displacements described by the theory, and this in turn has implications for the topology of the magnetic fields.

Finally, MHD possesses those conservation properties enjoyed by fluid mechanics and electromagnetism, namely:

- conservation of mass,
- conservation of momentum,
- conservation of energy (both mechanical and electromagnetic),
- conservation of magnetic flux.
List of symbols

\( \mu_0 \) permeability of free space \( \text{(N} \cdot \text{A}^2) \)
\( \eta \) resistivity of plasma
\( \rho \) average mass density of plasma \( \text{(kg} \cdot \text{m}^{-3}) \)
\( p \) pressure \( \text{(N} \cdot \text{m}^{-2}) \)
\( \gamma \) ratio of specific heats
\( v \) velocity of the fluid element \( \text{(m/s}) \)
\( J \) current density \( \text{(A} \cdot \text{m}^{-2}) \)
\( E \) electric field
\( B \) magnetic field

3. The Kalman filter

The Kalman filter (KF) \[9\] is an estimator for what is called the linear-quadratic Gaussian estimation problem, which is the problem of estimating the instantaneous stage of a linear dynamic system perturbed by a Gaussian random process-process noise, and using measurements linearly related to the state but corrupted also by a Gaussian random process-measurement noise. The resulting estimator is statistically optimal with respect to any quadratic function of estimation error.

Given a linear dynamical model in discrete form as

\[ x_{k+1} = A_k x_k + B_k u_k + w_k, \quad k \geq 0 \]  \hspace{1cm} (9)

with output

\[ y_k = C_k x_k + v_k, \] \hspace{1cm} (10)

where \( x_k \in \mathbb{R}^n \), \( u_k \in \mathbb{R}^m \), \( y_k \in \mathbb{R}^p \), and \( A_k, B_k, C_k \) are known real matrices of appropriate size. The input \( u_k \) and output \( y_k \) are assumed to be measured, and \( w_k \in \mathbb{R}^{n_k} \) and \( v_k \in \mathbb{R}^p \) are uncorrelated white noise processes with known variances and correlation given by \( Q_k \), and \( R_k \), respectively.

3.1. Estimation problem

Consider the discrete-time dynamical system described by (9) and (10). For this system, we take a state estimator of the form

\[ \hat{x}_{k|k} = \hat{x}_{k|k-1} + L_k (y_k - \hat{y}_{k|k-1}), \quad k \geq 0, \] \hspace{1cm} (11)

where \( L_k \in \mathbb{R}^{n \times m} \) and \( \hat{x}_{k|k-1} \) is the estimate of \( x_k \) based on observations up to time \( k - 1 \), with output

\[ \hat{y}_{k|k-1} = C \hat{x}_{k|k-1}. \] \hspace{1cm} (12)

In order to solve this problem a recursive procedure is used. The first step, is to project ahead \( x_{k-1|k-1} \) using (9)

\[ \hat{x}_{k|k-1} = A_{k-1} x_{k-1|k-1} + B_{k-1} u_{k-1}, \] \hspace{1cm} (13)
then, define the prior state estimation error by
\[ e_{k|k-1} = x_k - \hat{x}_{k|k-1}, \quad k > 0. \] (14)
Substituting (13) and (9) into (14) we obtain
\[ e_{k|k-1} = A_{k-1} e_{k-1|k-1} + w_{k-1}, \] (15)
now, define the prior error covariance matrix by
\[ P_{k|k-1} \triangleq E[e_{k|k-1} e_{k|k-1}^T], \] (16)
hence,
\[ P_{k|k-1} = A_{k-1} P_{k-1|k-1} A_{k-1}^T + Q_{k-1}. \] (17)
Next, define the state estimator error
\[ e_{k|k} \triangleq x_k - \hat{x}_{k|k}, \] (18)
consequently, the Kalman gain \( L_k \) minimizes
\[ J_k(L_k) = \text{tr}(P_{k|k}), \] (19)
where the estimation error covariance matrix \( P_{k|k} \in \mathbb{R}^{n \times n} \)
\[ P_{k|k} \triangleq E[(e_{k|k} - E[e_{k|k}])(e_{k|k} - E[e_{k|k}])^T]. \] (20)
As a result, the Kalman gain can be obtained by
\[ L_k = P_{k|k-1} C_k^T (R_k + C_k P_{k|k-1} C_k^T)^{-1} \] (21)
with the error covariance matrix update
\[ P_{k|k} = (I_n - L_k C_k) P_{k|k-1}. \] (22)
Summarizing the algorithm we have for \( k = 1, 2, \ldots \)

1. Project ahead the error covariance matrix and the estimated states:
   \[ P_{k|k-1} = A_{k-1} P_{k-1|k-1} A_{k-1}^T + Q_{k-1}, \]
   \[ \hat{x}_{k|k-1} = A_{k-1} \hat{x}_{k-1|k-1} + B_{k-1} u_{k-1}. \]
2. Compute the Kalman gain:
   \[ L_k = P_{k|k-1} C_k^T (R_k + C_k P_{k|k-1} C_k^T)^{-1} \]
3. Update the estimated states:
   \[ \hat{x}_{k|k} = \hat{x}_{k|k-1} + L_k (y_k - \hat{y}_{k|k-1}) \]
4. Update the error covariance matrix:
   \[ P_{k|k} = (I_n - L_k C_k) P_{k|k-1} \]
4. The ensemble Kalman filter

The EnKF is a sequential data assimilation method where the error statistics are predicted by solving the Fokker–Planck (35), which describes the time evolution of a probability density function of a model state, using a Monte Carlo or ensemble integration. The method was originally proposed by Evensen [5]. By integrating an ensemble of model states forward in time it is possible to calculate statistical moments like mean and error covariances whenever such information is required. Thus, all the statistical information about the predicted model state that is required at analysis times is contained in the ensemble. More details can be found for instance in [3,6,10].

The method is presented in three stages:

- representation of error statistics;
- prediction of error statistics;
- the estimation problem.

4.1. Representation of error statistics

The error covariance matrices for the prior and current estimate, $P_{k|k-1}$ and $P_{k|k}$, are in the classical KF defined in terms of the true state as

$$P_{k|k-1} = E[(x_k - \hat{x}_{k|k-1})(x_k - \hat{x}_{k|k-1})^T],$$  \hspace{1cm} (23)

$$P_{k|k} = E[(x_k - \hat{x}_{k|k})(x_k - \hat{x}_{k|k})^T],$$  \hspace{1cm} (24)

where $E[\cdot]$ denotes an expectation value. Now, for the EnKF assume that we have an ensemble of forecasted model states that randomly sample the model errors at time $k$. Let us denote this ensemble as $X_{k|k-1}$ and is defined by

$$X_{k|k-1} \equiv (\hat{x}^1_{k|k-1}, \ldots, \hat{x}^N_{k|k-1}),$$  \hspace{1cm} (25)

where the superscript denotes the ensemble member. Then, the ensemble mean $\overline{\hat{x}}_{k|k-1}$ is defined by

$$\overline{\hat{x}}_{k|k-1} \equiv \frac{1}{N} \sum_{i=1}^{N} \hat{x}^i_{k|k-1}. $$  \hspace{1cm} (26)

Since the true state $x_k$ is not known, and in order to write (23) and (24) in terms of (25), we therefore define the ensemble covariance matrices around the ensemble mean as follows: define the ensemble of prior estimation errors by

$$E_{k|k-1} \equiv (\hat{x}^1_{k|k-1} - \overline{\hat{x}}_{k|k-1}, \ldots, \hat{x}^N_{k|k-1} - \overline{\hat{x}}_{k|k-1}),$$  \hspace{1cm} (27)

and the ensemble of estimation errors by

$$E_{k|k} \equiv (\hat{x}^1_{k|k} - \overline{\hat{x}}_{k|k}, \ldots, \hat{x}^N_{k|k} - \overline{\hat{x}}_{k|k}).$$  \hspace{1cm} (28)

Hence,

\[
P_{k|k-1} \approx \hat{P}_{k|k-1} = \frac{1}{N-1} E[E_{k|k-1}E_{k|k-1}^T],
\]

(29)

\[
P_{k|k} \approx \hat{P}_{k|k} = \frac{1}{N-1} E[E_{k|k}E_{k|k}^T]
\]

(30)

which are averages over the ensembles. Thus, we can use an interpretation where the ensemble mean is the best estimate and the spreading of the ensemble around the mean is a natural definition of the error in the ensemble mean. Since the error covariances defined in (29) and (30) are defined as ensemble averages, there will clearly exist infinitely many ensembles with an error covariance equal to \( \hat{P}_{k|k-1} \) and \( \hat{P}_{k|k} \). Thus, instead of storing a full covariance matrix, we can represent the same error statistics using an appropriate ensemble of model states. Given an error covariance matrix, an ensemble of finite size will always provide an approximation to the error covariance matrix. However, when the size of the ensemble \( N \) increases the errors in the Monte Carlo sampling will decrease proportional to \( 1/\sqrt{N} \).

Suppose now that we have \( N \) model states in the ensemble, each of dimension \( n \). Each of these model states can be represented as a single point in an \( N \)-dimensional state space. All the ensemble members together will constitute a cloud of points in the state space. Such a cloud of points in the state space can, in the limit when \( N \) goes to infinity, be described using a probability density function

\[
\phi(x) = \frac{dN}{N},
\]

(31)

where \( dN \) is the number of points in a small unit volume and \( N \) is the total number of points. With knowledge about either \( \phi(x) \) or the ensemble representing \( \phi(x) \), we can calculate whichever statistical moments (such as mean, covariances, etc.) we want whenever they are needed.

The conclusion so far is that the information contained by a full probability density function can be exactly represented by an infinite ensemble of model states.

4.2. Prediction of error statistics

The EnKfE was designed to resolve two major problems related to the use of the EKF [1] with nonlinear dynamics in large state spaces. The first problem relates to the use of an approximate closure scheme in
the EKF, and the other to the huge computational requirements associated with the storage and forward integration of the error covariance matrix. The EKF applies a closure scheme where third- and higher-order moments in the error covariance equation are discarded. This linearization has been shown to be invalid in a number of applications. In fact, the equation is no longer the fundamental equation for the error evolution when the dynamical model is nonlinear. For a nonlinear model where we appreciate that the model is not perfect and contains model errors, we can write it as a discrete-time stochastic differential equation as

\[ x_{k+1} = \mathcal{M}(x_k) + \eta_k \]  

with \( \eta_k \) the model error at time \( k \) defined by

\[ \eta_k \triangleq G_k(x_k)\delta_k \]  

with \( G_k(x_k) \in \mathbb{R}^{n \times l} \) is a state-dependent matrix, where the covariance matrix \( Q_k \in \mathbb{R}^{n \times n} \) is defined as

\[ Q_k \triangleq E[G_k(x_k)G_k(x_k)^T] \]
and $\delta_k \in \mathbb{R}^l$ is a process we want to approximate as white noise. Eq. (32) implies that even if the initial state is known precisely, future model states cannot, since unknown random model errors are continually added.

Conceptually, the evolution of (31) can be modelled with the Fokker–Planck equation

$$ \frac{\partial \phi(x_k)}{\partial t} = -\nabla[A(x_k)\phi(x_k)] + \sum_{i,j} \frac{\partial^2}{\partial x_{k(i)} \partial x_{k(j)}} \left( \frac{Q_k}{2} \right)_{ij} \phi(x_k). $$

This equation does not apply any important approximations and can be considered as the fundamental equation for the time evolution of error statistics. A detailed derivation is given in [8]. The equation describes the change of the probability density in a local volume which is dependent on the divergence term describing a probability flux into the local volume (impact of the dynamical equation) and the diffusion term which tends to flatten the probability density due to the effect of stochastic model errors. If (35) could be solved for the probability density function, it would be possible to calculate statistical moments like the mean state and the error covariance for the model forecast to be used in the analysis scheme. The EnKF applies a so-called Markov chain Monte Carlo (MCMC) method to solve (35). The probability density can be represented using a large ensemble of model states. By integrating these model states forward in time according to the model dynamics described by (32), this ensemble prediction is
equivalent to solving the Fokker–Planck equation using a MCMC method. This procedure forms the backbone for the EnKF.

4.3. The estimation problem

In the standard KF estimation problem the definition of $P_{k|k-1}$ and $P_{k|k}$ are used. It is now given a derivation of the estimation problem for the EnKF using (29) and (30).

The EnKF performs an ensemble of parallel data assimilation cycles, using (11) as follows: for $i = 1, \ldots, N$

$$
\hat{x}_{k|k}^i = \hat{x}_{k|k-1}^i + L_{e_k} (y_k^i - \varphi(\hat{x}_{k|k-1}^i)),
$$

(36)
where $\mathcal{C}$ is the observation operator, which is permitted to be a nonlinear operator, and the observations $y_k^i = y_k + \epsilon^i$ are perturbed observations defined such that $\epsilon^i \sim \mathcal{N}(0, R_e)$. In the limit of an infinite ensemble the matrix $R_e$ will converge toward the prescribed error covariance matrix $R$ used in the standard KF.

Similar to the standard KF, in (36) $L_{ek}$ is defined as

$$L_{ek} = \hat{P}_{k|k-1}'\epsilon^T(\epsilon \hat{P}_{k|k-1}' \epsilon^T + R_e)^{-1}$$ (37)

with the difference that $\mathcal{C}$ can be nonlinear which is a powerful advantage compare to other nonlinear KF that are based on linearized models like EKF. Envision a situation where errors grow rapidly but saturate at low amplitude; the linear assumption of error growth in the EKF will result in an overestimate of the
prior error variance, but the differences among ensemble members will not grow without bound and thus should provide a more accurate model of the actual prior error statistics.

On the other hand, for a complex model with a high-dimensional state vector, explicitly forming $\hat{P}_{k|k-1}$ as in (29) would be computationally prohibitive. However, in the EnKF, $L_{e_k}$ can be formed without ever explicitly computing the full $\hat{P}_{k|k-1}$. Instead, the components of $\hat{P}_{k|k-1} \mathcal{C}^T$ and $\mathcal{C} \hat{P}_{k|k-1} \mathcal{C}^T$ of $L_{e_k}$ are computed separately. Define

$$\mathcal{C}(\hat{x}_{k|k-1}) \triangleq \frac{1}{N} \sum_{i=1}^{N} \mathcal{C}(\hat{x}_{k|k-1}^i)$$

(38)
which represents the mean of the estimate of the observation interpolated from the background forecasts. Then

\[
\hat{P}_{k|k-1}^{\tilde{C}} \triangleq \frac{1}{N-1} \sum_{i=1}^{N} (\tilde{x}_k^i - \tilde{x}_{k|k-1})(\tilde{C}(\tilde{x}_k^i) - \underline{C}(\tilde{x}_{k|k-1}))^T \tag{39}
\]

and

\[
\bar{C} \hat{P}_{k|k-1}^{\tilde{C}} \bar{C}^T \triangleq \frac{1}{N-1} \sum_{i=1}^{N} (\underline{C}(\tilde{x}_k^i) - \bar{C}(\tilde{x}_{k|k-1}))(\underline{C}(\tilde{x}_k^i) - \bar{C}(\tilde{x}_{k|k-1}))^T. \tag{40}
\]
After the estimation is done, a short-range forecast is computed by running the physics first-principle-based model (32) until new measurements are taken, then the data assimilation cycle is repeated.

5. Numerical results

In order to investigate how the EnKF operates in MHD systems, we took the ideal MHD system equations (1)–(6) with (8), setting the boundary conditions of the right-hand side such that it simulates the magnetosphere around the Earth. This system was simulated with the VAC code [11] with the
following parameters:

- grid size: $34 \times 54$;
- initial conditions of the state space variables:
  - mass density, $\rho = 1.0 \text{ kg/m}^3$;
  - velocity in $x$- and $y$-directions, $v_x = 20 \text{ m/s}, v_y = 0 \text{ m/s}$;
  - pressure, $p = 1.0 \text{ kg/m}^2\text{s}^2$;
  - magnetic field in $x$- and $y$-directions, $B_x = 0 \text{ mT}, B_y = 1.0 \text{ mT}$;
- ratio of specific heats, $\gamma = 5/3$;
- simulation sampling time, $1 \times 10^{-4} \text{ s}$;
• data assimilation sampling time, $4 \times 10^{-4}$ s;
• spatial discretization method: total variation diminishing Lax–Friedrich-TVDLF, using the Powell’s scheme to maintain $\nabla B = 0$.

As a result the order of the system is 11,016, six state space variables and $34 \times 54$ gridpoints. To excite the system, a square sinusoidal wave for $B_y$ varying from 1 to 1.5 mT, and $V_x$ from 20 to 30 m/s, were generated at the left-hand boundary, simulating a magnetic storm, and the right-hand boundary was set such that it simulates a bowshock like the one formed in the magnetosphere around Earth. Therefore the boundary conditions for the VAC are set as seen in Table 1.

Fig. 1 depicts a general scheme of the EnKF implementation by running Matlab and the VAC code simultaneously. Since we can see in the scheme we did not need any extra code for the model; anyhow, we had to write the code of the EnKF in Matlab, and some code to read and write the VAC’s files where the initial and final conditions in each data assimilation sampling time are saved. As a result, we have got a modular data assimilation system where the nonlinear model integration module is executed by the VAC code, while the data assimilation module for Matlab. This is one of the motivation for using the EnKF, because it is quite straightforward to implement, and the results are very confident.

To investigate the performance of the EnKF in MHD systems a magnetic storm around the earth was simulated by changing the boundary conditions as mentioned above. We study three cases, for 10, 100, and 200 measurement points, and for each case we use 50, 150, and 300 ensemble members, respectively.

Fig. 2 shows the root mean square error (RMSE) of the state space estimation for the whole scenarios. On the first column, when 50 ensemble members are used, it can be seen that the data assimilation process always crashes independent of the number of measurement points, this is due to the fact that the number of ensemble members are not enough to give a good approximation of the error covariance matrix $P_{k|k-1}$, contrary to the cases of 150 and 300 ensemble members which seems to be enough to obtain a good representation of the error covariance matrix $P_{k|k-1}$; therefore, it is difficult for the EnKF approach to find an appropriate filter gain. As a result the EnKF takes the system to regions where the model integration becomes unfeasible.

In the other cases, 150 and 300 members, the data assimilation process works more reliable, even for the cases with 10 measurement points. Although the worst performance is for the case of 10 measurement points with 150 and 300 ensemble members, the results are close to the other cases indicating that the number of ensemble members is more important than the number of measurement points; however, the number and location of the measurement points are important as well. In the experiments, the location of the measurement point are chosen such that at least half of the points were located in the right-half plane around the bowshock where the more drastic changes occurs, this guarantees that the data assimilation process will track the big changes in the system, otherwise the estimation would be very poor.

On the other hand, in two of the cases of 150 and 300 ensemble members, we observe how the EnKF struggle to correct the trajectory of the system when the perturbation reaches the bowshock (magnetosphere). In the first 10 data assimilation sampling times we see that the RMSE decreases, this is due to the fact that the initial conditions are close to the current ones and the perturbation is far from the bowshock. Then after, the RMSE increases because the perturbation reaches the bowshock originating big changes in the dynamics of the system. Finally, the EnKF manage to keep the estimated system stable and close to the real one.
Furthermore, Figs. 3–5, and 6–8 depict in detail how the magnetic field and the plasma velocity around the earth are estimated, respectively, for different cases. It can be seen clearer that the more ensemble members and measurement points are taken, the better the estimation is, as expected.

6. Conclusions

In this paper, we introduced a new area of application for the EnKF, space weather forecast. The EnKF is an extension of the KF to the nonlinear case, where based on a Monte Carlo simulation approach the measurement and process noise errors are propagated. One of the advantages of the EnKF is its facility to be implemented as a modular system, with mainly two modules, namely, the model simulator and the data assimilation module. This scheme permits the use of specialized codes for each task, making the EnKF more robust and reliable.

The EnKF has shown an acceptable performance for the data assimilation experiment study in this paper. The results are very promising, despite that simplification has been done with respect to the real space weather forecast problem. One interesting result we can draw from this experiment, is that, if we are able to place strategically some measurement points in the magnetosphere around the Earth, that would be enough to expect a good estimation of the dynamics of the system, assuming that the models we used are correct. We mention this, because in the real case there are very few satellites out there in the space which can be used as measurement points. Nevertheless, notice that when we say few measurement points compared to the order of the system, this could be a huge number for practical and economical issues. Therefore, the problem of how to get measurements of the physical variables of the space plasma close to Earth has to be solved before any data assimilation technique can be used in real life. Another solution is to design estimators for local areas around the measurement points as suggested in [2].

On the other hand, another drawback of the EnKF despite the fact that the statistics can be approximated with a small ensemble, is that it is still very demanding computationally. Anyhow, the order of complexity is similar to other nonlinear KFs [5]. Also a lot of research has to be done in this direction. Furthermore, the knowledge of the process and measurement noise are needed in order to have more accurate results.
