## Abstract

We investigate the bias in CRSP data due to missing returns for many stocks delisted from Nasdaq. We find that missing returns are far more common when the delisting is for reasons of poor performance, that the missing returns are large and negative on average, and that delisted stocks undergo a large decrease in liquidity. This implies a bias for studies using Nasdaq data 4.7 times larger than the delisting bias previously documented for CRSP's NYSE/AMEX data. We estimate that using a corrected return of  $-55\%$  for missing performance-related delisting returns will correct the bias.

We revisit previous work which found a size effect in the Nasdaq data and find that, after correcting for the delisting bias, there is no evidence that there was ever a size effect among Nasdaq stocks. Since small Nasdaq stocks are both the smallest and the most distressed stocks for which we have reliable data, our results are not consistent with most risk-based explanations of the size effect.

---

\*We thank Dmitry Davydov for superb research assistance. We also thank Mark Mitchell, Rene Stulz, an anonymous referee, and participants at a seminar at the University of Michigan for helpful comments. # 1 Introduction

Each year, many of the stocks traded on Nasdaq are delisted from the system and cease to be traded there. Delistings occur for a number of reasons including merger and acquisition, bankruptcy, liquidation, or migration to another exchange. They usually coincide with significant firm-specific events, so the returns associated with delistings are often sizable. Further, a stock's liquidity can change dramatically upon delisting, affecting the price at which shareholders can sell their shares. The Center for Research in Security Prices (CRSP) attempts to systematically collect delisting returns. However, the task is difficult, and many returns are not collected. Some categories are missed more often than others. Specifically, delisting returns associated with poor firm performance (e.g., bankruptcy or failure to meet capital requirements) are missed much more often than returns associated with neutral or good firm performance (e.g., merger, acquisition, or migration to another exchange). Since most of the missing delisting returns are associated with negative events, a significant bias exists in the data.

We study this delisting bias in two ways. First, we document the magnitude of the bias. We investigate when and how often delisting returns are not collected by CRSP, and we estimate the average size of the missing returns. In this way, we extend to Nasdaq the work of Shumway (1997) which examines the delisting bias in CRSP's NYSE and AMEX data. The bias in the Nasdaq data is much larger—while 1.2% of NYSE and AMEX stocks are delisted for poor performance each year on average, 5.6% of Nasdaq stocks are delisted on average each year for similar reasons. Delistings are most frequent for the smallest Nasdaq stocks—on average, 2.95% of stocks in the smallest five percent of Nasdaq stocks are delisted each month. Using over-the-counter prices taken from the *Pink Sheets*, we locate return data for 63% of these missing returns. The average return for the other 37% is presumably even lower. We also document a substantial decrease in liquidity upon delisting which further decreases the effective value of the stock. Accounting for all these factors, we estimate the average effective return for stocks delisted from Nasdaq for performance reasons to be  $-55\%$ . Researchers can use this estimated return to correct the

CRSP database for the delisting bias.

Second, we explore the implications of this delisting bias for the size effect first documented by Banz (1981) and Reinganum (1981). We revisit the work of Lamoureux and Sanger (1989) which found evidence of a size effect in the Nasdaq data, and we find that the results are sensitive to the delisting bias since delistings occur more frequently among smaller stocks. After correcting for the bias, virtually no evidence of a size effect remains for the full sample period 1972-1995. We repeat the analysis for the two subperiods covering the years 1973-1985 and 1986-1995, and we find no evidence of a size effect in either subperiod. Hence, there is no evidence that there was ever a size effect among Nasdaq stocks.

The results are relevant to the debate over the interpretation of the size effect. Many of the explanations proposed for the size effect assert that small firms earn high average returns because they are fundamentally riskier than large firms. For example, Berk (1995) argues that size proxies for unmeasured systematic risk and both Chan and Chen (1991) and Fama and French (1995) contend that the higher returns are compensation for the higher risk of financial distress among small firms. Dichev (1998), on the other hand, finds evidence inconsistent with the distress risk explanation of the size effect. Small Nasdaq stocks are ideal for examining the size effect because they are, as a group, the smallest and most distressed stocks for which we have reliable data. Presumably, the size effect should be most pronounced for this sample of stocks. Using delisting frequency as a proxy for distress, we show that size and distress are correlated among Nasdaq stocks. Consequently, our finding of no size effect among Nasdaq stocks is evidence against the risk-based explanations of the size effect. This is consistent with Dichev (1998) as well as the assertions of Lo and MacKinlay (1990) and Black (1993) that the size effect is an example of a data-snooping bias rather than a fundamental economic phenomenon.

The delisting bias also has implications for studies which compare the average returns of NYSE and Nasdaq stocks. Reinganum (1990) first reported that small NYSE firms have average annual returns about 6% higher than Nasdaq firms of the same size. Loughran

(1993) attributes about 60% of the difference to the poor performance of initial public offerings, while Fama, French, Booth, and Siquefield (1993) attribute the difference to a higher probability of distress for NYSE firms. Correcting for the delisting bias documented here increases the return differential further since the delisting bias is larger in the Nasdaq data. This increases the return-differential puzzle at the center of this literature.

The paper proceeds as follows. Section 2 documents the delisting bias in Nasdaq data, section 3 estimates an average return that researchers can use to correct for the bias, section 4 analyzes the implications of the bias for the size effect, and section 5 concludes.

## 2 The Delisting Bias in CRSP's Nasdaq Data

### 2.1 The Frequency of Missing Delisting Returns

To assess the frequency with which delisting returns are omitted from CRSP, we examine daily returns for all the stocks in CRSP's Nasdaq database from 1972 to 1995. Whenever a stock is coded as having been delisted, we record whether a delisting return is given.<sup>1</sup> We classify delisting codes 500 and 505 through 588 as performance-related (i.e., a negative change for the firm). We do not classify delisting codes 501 and 502 (migration to the NYSE or AMEX) as performance-related because these events are usually positive changes for a firm (see Baker and Edelman (1991)). Table 1 shows the number of delistings for each category established by CRSP, and performance-related reasons are the most common given for delisting, followed by merger and migration to the NYSE or AMEX.<sup>2</sup>

No reason is given for 26% of the performance-related delistings. This designation exists largely because CRSP assigned all distressed delistings a code of 5 prior to 1987, so the

---

<sup>1</sup>In the 1996 CRSP monthly files, CRSP has added partial-month returns to the delisting return field, which are calculated using the last recorded month-end price and the last day price of each delisted security. While CRSP calls these returns "delisting returns," they should not be confused with the delisting returns we examine here. CRSP's returns use only pre-delisting prices. Our delisting returns use post-delisting prices and so include the effect of the delisting.

<sup>2</sup>Although there are relatively few bankruptcy-related delistings recorded by CRSP, many of the firms delisted for other reasons are already bankrupt when they delist. It is common, for example, for a firm to file for bankruptcy and then be delisted for failing to meet Nasdaq's financial guidelines.

events in this category occur for the same reasons as the other events in the table. Since most of the others are performance-related, we classify all of the “reason unavailable” delists as performance-related.

The pattern of missing returns is striking. The three non-performance-related categories have virtually no missing returns. Less than 1% are missing for merger, exchange, or movement to the NYSE or AMEX. On the other hand, virtually all (99.8%) returns are missing for performance-related delistings. Hence, the missing returns will almost certainly introduce a bias. The much smaller category of liquidations is a special case. While 61.0% are missing returns, CRSP gives them a code indicating the liquidation was announced before the delisting. Consequently, information about liquidation was incorporated into the stock price before delisting, and we do not expect the missing returns to be significantly biased.

Performance-related delistings are much more frequent among Nasdaq stocks than among NYSE and AMEX stocks. There are, on average, 220 performance-related delistings from Nasdaq each year. By contrast, Shumway (1997) finds only 32 such delistings each year from the NYSE and AMEX combined. This translates to 1.2% of NYSE and AMEX stocks per year on average as opposed 5.6% of Nasdaq stocks, and so we expect the Nasdaq delisting bias to be about 4.7 times larger than the NYSE and AMEX bias.

The fraction of Nasdaq stocks delisted each year for performance reasons does not appear to be decreasing over time. Table 2 lists the number of performance-related delists, the number of firms, and the ratio of delists to listed firms each year. Most of the missing returns occur in the second half of the eighties and the early nineties. There are also an extraordinary number in 1973. This does not appear to be a case of CRSP miscoding since the number of delists for other reasons (e.g. merger, liquidation) in that year does not appear abnormal.

## 2.2 Are Delistings Anticipated?

If impending delistings are announced while the stock is still trading, then the missing returns may not introduce a bias. At the announcement, the effect of the impending delisting will be incorporated into the price of the stock, and we can expect the unobserved return on the delisting date to be unimportant. It is, therefore, necessary to determine how frequently investors know about impending delistings. To do this, we searched Bloomberg's company news database for articles about the 159 firms which were delisted in 1993 for performance-related reasons. Only 2 had stories that indicated any pre-delisting announcement. 41 stories actually indicated that the delisting was a surprise. For 81 firms, we found stories about the company, but no mention of delisting, for 28 we found no stories at all, and for 7 we found stories about the impending merger or liquidation (which implies an impending delisting). Therefore, it appears that most delisting events are unanticipated.

## 2.3 Temporary Delistings

In many cases, stocks which are delisted from Nasdaq are subsequently relisted on Nasdaq. In these cases, CRSP gives the stocks a delisting code that indicates that the stocks are actively traded (after the stocks are relisted). When a stock ceases trading for ten or fewer trading periods, CRSP usually calculates a return for the period based on the price before and after the non-trading interval. When the non-trading interval is more than ten periods, CRSP's stated policy is to ignore any change in price over the interval, and the return for the non-trading interval is coded as missing. In many cases, CRSP does not calculate a return even when the non-trading interval is less than ten periods.<sup>3</sup> We found 869 cases of temporary delistings with missing returns. Some of the non-trading intervals are quite

---

<sup>3</sup>Consider, for example, the case of Lexicon Corporation of Fort Lauderdale, Florida (CRSP permno = 49286). On April 8, 1993, Lexicon announced that it had been delisted by Nasdaq because it failed to meet their requirements for continued listing. Lexicon had been granted an exemption to Nasdaq's listing requirements, but its exemption expired on March 31. Its stock price was \$2.00 at the end of March. On August 2, Nasdaq's hearing-review committee decided to allow Lexicon's stock to be relisted. By the end of August the stock was trading at \$1.625. While Lexicon's stock lost 19% of its value over the five-month period that it was not listed, CRSP does not record a return for the interval.

long: the longest is over 20 years, and 595 are longer than 10 months.

Dealing with temporary delistings is somewhat problematic. One cannot simply calculate a return using CRSP price data before and after the non-trading interval since CRSP could have done so and presumably chose not to for good reasons.<sup>4</sup> Similarly, we do not attempt to determine a return from other sources since the period is usually too short to collect accurate data. The task is further complicated because these delistings are revealed to be temporary only after the firm is relisted. Therefore, to treat temporary delistings differently than permanent delistings would be to condition on a future event which is not known with certainty at the time of delisting, and would impose an unacceptable look-ahead bias.

Consequently, we conclude that the best way to deal with temporary delistings is to treat them in the same way we treat permanent delistings. We include temporary delistings in our sample of delistings even though CRSP does not explicitly code them as delistings. Because temporary delistings are not given a delisting code, we are unable to classify them precisely. It seems most likely that the majority occur for performance-related reasons, so we classify them as performance-related delistings. Including temporary delistings yields a total of 5,048 missing returns for performance-related delistings.<sup>5</sup>

### 3 Correcting for the Delisting Bias

#### 3.1 Delisting Prices from the Pink Sheets and other Sources

We collected over-the-counter price data for 3,330 stocks permanently delisted between 1977 and June of 1994 from semi-annual summaries of the *Pink Sheets*. This sample period is shorter than CRSP's Nasdaq sample period. It begins in 1977 because *Pink Sheets* data

---

<sup>4</sup>For instance, it is not clear that we are dealing with the same security or even the same firm before and after the temporary delisting. In at least some cases, the firm is reorganized during the delisting, and the old equity is declared worthless and new equity issued. It is also highly likely that temporarily delisted firms execute reverse stock splits which make the pre- and post-delisting prices incomparable.

<sup>5</sup>869 temporary delistings plus 4179 permanent delistings with missing returns equals a total of 5048 delistings.

is not available to us before that time, and it ends in June 1994 to ensure that at least 4 issues of the semi-annual *Pink Sheets* are available following delisting.

The *Pink Sheets* are published by the National Quotations Bureau, and give bid and ask quotes supplied by broker/dealers that maintain inventories in the stocks in which they specialize. Data in the *Pink Sheets* are not completely reliable. Because there is no mechanism to force dealers to honor the quotes they post in the *Pink Sheets*, some quotes may not reflect the prices at which dealers are willing to trade. But, while they are imperfect, there is no alternative source for valuing stocks that no longer trade on organized exchanges.

The *Pink Sheets* sometimes list more than one bid and ask price for a security when more than one dealer is willing to trade the security. We calculate the price in this case as an average of the highest bid, the lowest bid, the highest ask, and the lowest ask prices. Prices for delisted stocks are usually not available immediately after delisting. We use the first price found if it is within 2 years of the delisting. Where price data is not available within 2 years, we drop the observation. Where the calculated delisting return appears to be an outlier, we examine the observation more closely using other sources such as *Bloomberg*, and the *Directory of Obsolete Securities* (1993) published by the Financial Stock Guide Service. We found many instances where firms executed reverse splits to boost their stock price so they could be relisted on Nasdaq. Whenever we identified a split, we adjusted the subsequent prices. Insofar as we may not have detected all such splits, some of our recorded prices and returns may be too high, which will understate the magnitude of the bias. We also checked the *Directory of Obsolete Securities* for all stocks that did not have price quotes in the *Pink Sheets*. We identified 201 securities that became worthless within 5 years of delisting and we assigned a return of  $-100\%$  to them.

All told, we collected returns for 63% of delisted stocks (2,107 out of 3,330). Table 3 summarizes the returns. The mean returns are fairly uniform across the most populous categories with the average across all categories being  $-26.3\%$ , and the overall median being  $-30.0\%$ . The distribution of delisting returns has both a mass point at  $-100\%$  and

a fat upper tail. Mean returns for the five most common categories are all significantly different from zero at a high confidence level, and almost all of the other estimated means are negative, many significantly so. No estimated mean is significantly positive.

### 3.2 Selection Bias in the Sample of Identified Returns

Our sources yielded data on 63% of the stocks with missing delisting returns. To estimate the average delisting return, we must make an assumption about the 37% for which we found no prices. We could assume that the unlocated returns are the same as the ones we found and assign an average return of -26.3% to all of them. However, the delisting prices we found are not a random sample; they are more likely to be for firms which suffered the least serious performance deterioration, and the 37% we did not find are almost certainly from firms which performed more poorly on average. The fact that we found no trace of them suggests that many became worthless. Alternatively, we could assume that all firms we could not find became completely worthless, but, this is almost certainly too negative.

Rather than make either of these extreme assumptions, it seems reasonable to assume that half of the stocks for which we could not find data are similar to the stocks for which we did find data, and the other half became worthless. The first group is then assigned an average return of -26.5%.<sup>6</sup> The second group is assigned a return of -100%. Incorporating this, we get an average delisting return of

$$.63(-26.3) + .37(.5(-100.0) + .5(-26.5)) = -40\%. \tag{1}$$

Later, we perform a sensitivity analysis for this assumption.

---

<sup>6</sup>This figure is calculated by averaging the category-specific mean returns in Table 3 weighted by the frequency with which the unfound returns fall into each category.

### 3.3 Liquidity Effects of Delisting

Delisting from Nasdaq has a dramatic impact on liquidity if the stock is not subsequently listed on the NYSE or AMEX which means that an investor must sell the stock at a lower price after delisting than was possible before. To account for this, we examine the increase in the bid-ask spread by looking at the 320 stocks for which bid-ask data was available in the *Pink Sheets* and for which bid-ask data was also available in CRSP for at least one of the last three days that the stock was listed. In the rare instances in which more than one set of bid and ask quotes was given in the *Pink Sheets*, we use the average bid-ask spread. Defining the relative bid-ask spread as

$$\frac{\text{ask} - \text{bid}}{(\text{ask} + \text{bid})/2}, \quad (2)$$

we find that the mean relative bid-ask spread increases from 0.41 to 0.82 when a stock is delisted for performance reasons. The median relative bid-ask spread increases by an even larger amount, from 0.33 to 0.86.<sup>7</sup>

### 3.4 Calculation of a Corrected Delisting Return

To avoid a delisting bias in empirical work using CRSP's Nasdaq data, a researcher must account for all the factors discussed above. We now compute a corrected delisting return that can be used to do this, and we call this return  $R_{Corr}$ . Consider a stock listed on Nasdaq at price  $P$  that can be sold at the bid price of  $P(1 - .41/2) = .795P$ . After delisting, the stock's price drops 40% to  $P(1 - .40)$ , and it can then be sold at the bid price of  $P(1 - .40)(1 - .82/2) = .354P$ .<sup>8</sup> The corrected delisting return, i.e., the total change in

---

<sup>7</sup>The bid-ask spread calculations performed here use quoted spreads rather than effective spreads. Since we know little about effective spreads for *Pink Sheet* stocks, it is difficult to know whether the increase in spreads around delisting would be enlarged or diminished by accounting for effective spreads.

<sup>8</sup>At first blush, it may appear that this analysis is questionable because it assumes that stocks with  $-100\%$  returns have relative bid-ask spreads of 0.82 following delisting. However, the relative bid-ask spread after delisting is actually irrelevant for these stocks—after delisting, both the bid and the ask prices are 0 regardless of the assumed bid-ask spread and the relative bid-ask spread is undefined. Consequently, this calculation actually makes no assumption at all about the post-delisting relative bid-ask spread of

the wealth of an investor holding the stock through delisting is, therefore, <sup>9</sup>

$$R_{Corr} = \frac{.354P - .795P}{.795P} = -55\%. \quad (3)$$

Researchers can correct for the delisting bias by using this return whenever a performance-related delisting return is missing from CRSP's Nasdaq database.

## 4 Implications for the Size Effect

Banz (1981) and Reinganum (1981), were the first to document that stocks with smaller market capitalizations have higher average returns on average and that the effect is concentrated primarily in the smallest stocks. Since Nasdaq stocks have smaller market capitalizations on average than other listed stocks, they are of particular interest in understanding the size effect, and previous work has found a size effect among Nasdaq stocks. It is reasonable to suspect that delistings are concentrated disproportionately among smaller firms, and so the delisting bias may inflate the apparent returns to portfolios of smaller stocks. In this section, we investigate whether the apparent size effect among Nasdaq stocks is sensitive to correction of the data for the delisting bias.

Table 4 demonstrates that delistings are, in fact, more common for small stocks than for large ones. We assign all Nasdaq stocks to one of twenty portfolios each year based on their market capitalization at the end of the previous year. The table shows that performance-related delistings are more frequent among smaller Nasdaq stocks and that they are large and economically significant for the smallest portfolios. On average, 2.95% of stocks in the smallest portfolio are delisted each month, and 1.59%, 1.15%, and 0.87% are delisted each

---

worthless stocks.

<sup>9</sup>To double-check our method of including bid-ask spread effects, we also did the calculations a second way. Using the subset of firms for which we had both pre-delisting and post-delisting bid-ask data, we calculated bid-to-bid returns which incorporate the bid-ask spread change directly into the analysis. The mean bid-to-bid return was  $-41.6\%$ . After allowing for firms with returns of  $-100\%$ , and after allowing for the 37% of firms for which we could find no data, we arrived at a corrected delisting return virtually identical to this one.

month, on average, from the next 3 smallest portfolios.

Lamoureux and Sanger (1989) calculate average monthly returns for portfolios of Nasdaq stocks and conclude that there is a size effect among Nasdaq stocks. We repeat that work using the same methodology. Table 4 displays statistics for the returns of the twenty size portfolios formed as noted above. Mean monthly returns are calculated first using the unmodified CRSP data, and then they are recalculated using the the corrected CRSP data where a return of  $-55\%$  is inserted for all performance-related delistings which do not have return data in the CRSP database. Both delisting and temporary delisting returns are corrected.

As in Lamoureux and Sanger (1989), the unadjusted CRSP returns show a distinct pattern of higher returns for the smaller size portfolios. Our numbers differ from theirs somewhat because of the different sample periods. (Later, we redo the analysis for their sample period.) The smallest size portfolio has an average monthly return of  $3.79\%$ , which is well above the mean for all portfolios, and very significant economically. Each of the five smallest portfolios gives some indication of an abnormally high average return. When the data are corrected for the delisting bias, however, the abnormal returns are dramatically reduced. The mean return for the smallest size portfolio drops to  $1.97\%$  (a reduction of  $48\%$ ), and only the two smallest portfolios give any indication of a higher mean return.

To test the significance of these returns, we run a dummy regression where the dependent variable is the return of each portfolio each month concatenated with the mean return of all portfolios each month, and the independent variables are a constant and twenty dummies—one for each size portfolio. In this regression, the t-statistic for each dummy variable is a test of whether the mean return for that portfolio is significantly different from the mean return of all the portfolios. T-statistics for the dummies are reported in the last two columns of Table 4. They indicate that the returns for the two smallest portfolios are significantly different from the overall mean when no delisting correction is used. When the delisting return is applied, however, none of the portfolio dummies are significant. At the bottom of the table, the F-statistic is reported for the significance of the overall regression, which

simultaneously tests the significance of all the dummies. For the uncorrected CRSP data, the F-test is highly significant, rejecting the null hypothesis that all dummy coefficients are zero. The delisting correction, however, reverses the inference dramatically, so that there is no evidence to reject the null hypothesis that all the dummy coefficients are zero. Consequently, the delisting bias is crucial for the evidence of a size effect in Nasdaq for the years 1972 – 1995.

Fama and French (1992), and Dichev (1998) as well as others have suggested that the size effect has diminished in recent years, which raises the possibility that the size effect may survive the delisting correction in the earlier part of the sample. To address this question, we redo the analysis for the subperiods 1973-1985 and 1986-1995. The first corresponds to the sample period of Lamoureux and Sanger (1989) and makes the results directly comparable. Table 5 shows results of the size analysis for the subsamples. Against expectations, the size effect is stronger (in some ways) in the later subperiod than in the earlier one. The mean return to the smallest portfolio is 4.98% in the later subperiod as opposed to only 2.87% in the first. Mean returns for the other size portfolios are not as easily compared since the mean return for all portfolios is lower in the later subperiod, but, the five smallest portfolios in the later subperiod give some indication of above-average returns. Moreover, the F-statistic for the test that all means are equal is 3.72 ( $p=0.0001$ ) for the second period and 0.99 ( $p=0.470$ ) for the first, further indicating that the apparent size effect (before correcting for the delisting bias) has not diminished over time.

Table 5 also shows that correcting for the delisting bias essentially eliminates the evidence for the size effect in both subperiods. Again, only the two smallest size portfolios show evidence of above-average returns, and the overall F-statistic is statistically insignificant in both subperiods (0.08 in the earlier one, and 0.78 in the later one). Thus, the subperiod results reinforce the results from the full sample period. It appears that there was never a significant size effect in Nasdaq stocks. Any apparent size effect (in the subperiods as well as the full sample) can be attributed to the bias introduced into the data by the missing delisting returns.

## 4.1 Interpretation of the size effect

The meaning of the size effect has been debated since it was first identified, and our results throw additional light on the issue. One explanation for the size effect is that the higher returns earned by small firms are compensation for the higher riskiness of small firms. Berk (1995) argues that size is functioning as a proxy for the unobservable systematic risk of these firms. Similarly, Chan and Chen (1991) and Fama and French (1995) argue that the higher average returns of smaller firms are compensation for the higher risk of financial distress among small firms. Dichev (1998), on the other hand, finds evidence inconsistent with a distress explanation of the size effect.

Small Nasdaq stocks are ideal for examining the size effect because they are, as a group, the smallest and most distressed stocks for which we have reliable data. Presumably, the size effect should be most pronounced in this sample of stocks. Table 4 offers evidence that size and the risk of distress are, in fact highly correlated among Nasdaq stocks since the smallest size portfolios have a much higher delisting frequency than the larger size portfolios. Therefore, our finding of no size effect among Nasdaq stocks is evidence against the hypothesis that the size effect is due to the systematic pricing of the distress risk of smaller firms. This is consistent with the findings of Dichev (1998). Our results also tend to support the assertion of Lo and MacKinlay (1990), and Black (1993) that the size effect is an example of a data-snooping bias. Under that hypothesis, we should not expect to see the size effect outside of the sample in which it was first identified. Because Nasdaq data provides just such an out-of-sample test, the absence of a size effect there tends to support the data-snooping hypothesis.

## 4.2 Sensitivity Analyses

The analysis has had to use data from sources that are incomplete and somewhat unreliable, which has necessitated a number of assumptions. Now, we analyze the sensitivity of the results to these assumptions. Table 5 displays results of the size analysis under a series of alternative assumptions. (The results for the 1973-1985 and 1986-1995 subperiods have

already been discussed.)

In the analysis to this point, we correct for both permanent and temporary delistings. We feel this is appropriate because the two are indistinguishable at the time of delisting, and it is only later that the investors learn that a delisting is temporary. It is possible, though, that temporary delistings are different intrinsically and therefore warrant a different corrected return. To judge the importance of this concern, Table 5 shows results of the size analysis when only permanent delistings are corrected and temporary delistings are assigned a return of 0% (clearly an upwardly biased estimate of the true return). This makes only a small difference to the results. While the return on the smallest portfolio increases from 1.97% to 2.23%, the overall F-statistic is still completely insignificant, so the inferences are unchanged.

We assumed that half of the stocks for which we could not find post-delisting returns experienced  $-100\%$  returns while the other half had the same average return as the stocks for which we found post-delisting returns. Table 5 shows results when it is assumed that all stocks with missing returns became completely worthless (making  $R_{Corr} = -66\%$ ), and the case where all stocks with missing returns had the same return as the stocks we found (making  $R_{Corr} = -43\%$ ). Again, the average returns to the smallest portfolios change somewhat, but the overall inferences are unaffected.

Last, we address the possibility of a bias in measured returns due to bid-ask bounce. Blume and Stambaugh (1983) suggest that bid-ask bounce may bias analysis of the size effect since the bias will be most severe for small stocks which are more thinly traded. They recommend using buy and hold returns of up to a year to eliminate the bias. We recalculate the size portfolio returns using annual buy and hold returns. All stocks are sorted into size portfolios each year as before, but annual returns rather than monthly returns are calculated for each stock, where the annual returns are calculated by compounding the monthly returns. When a stock is delisted, its returns subsequent to delisting are replaced by returns for CRSP's value-weighted index of all Nasdaq, NYSE and AMEX stocks. To facilitate comparison, we convert the annual return to an equivalent compounded monthly

return and report these in Table 5. The size effect is weakened in the uncorrected data, but is still discernable. After correction, the measured size effect is reduced even further, to the point where it is almost unobservable. The F-statistic for the overall regression becomes even less significant, and only the very smallest portfolio gives any sign of having an above-average return. This suggests that what little evidence of a size effect remained after correction for the delisting bias in the previous analysis is at least partially explained by bid-ask bounce in the monthly data, which further strengthens our overall results.

### 4.3 Does the Corrected Return Vary by Firm Size?

It is reasonable to speculate that the corrected delisting return may vary by firm size. This could happen if small firms have  $-100\%$  returns after delisting more often than large firms, or if small firms with *Pink Sheet* data have lower returns, or if small firms experience a larger increase in their bid-ask spread. Any of these could introduce a bias into the corrected analysis.

To address this concern, we first write a single equation for the corrected return. Define  $F$  to be the fraction of firms for which we were able to find post-delisting returns, define  $R_F$  to be the average return of the firms for which we found post-delisting returns, and define  $S_0$  and  $S_1$  to be the pre-delisting and post-delisting relative bid-ask spreads respectively.  $R_{Corr}$  is then given by:

$$R_{Corr} = \frac{F(1 + R_F)\left(1 - \frac{S_1}{2}\right) + .5(1 - F)\left[(1 + R_F)\left(1 - \frac{S_1}{2}\right) + (1 - 1.00)\right]}{\left(1 - \frac{S_0}{2}\right)} - 1.^{10} \quad (4)$$

---

<sup>10</sup>The denominator represents what an investor could have sold one dollar of stock for before delisting taking into account the relative bid-ask spread. The numerator represents what the same amount of stock could be sold for after delisting. The first term in the numerator represents firms for whom we found post-delisting returns, the second term represents firms for whom we did not find returns and are presumed to be like the firms for whom we did find returns, and the term containing  $(1 - 1.00)$  represents firms for whom we did not find returns and are presumed to have become worthless.

Simplifying and re-arranging, we can write:

$$R_{Corr} = .5(F + 1)(1 - R_F) \left( \frac{1 - \frac{S_1}{2}}{1 - \frac{S_0}{2}} \right). \quad (5)$$

The corrected return is a function of three factors:  $F$ ,  $R_F$ , and  $(1 - \frac{S_1}{2})/(1 - \frac{S_0}{2})$ . If these factors do not vary by size, then the corrected return also does not vary by size.

Table 6 displays information about each of the factors for the size portfolios. For the first two factors, all Nasdaq firms are grouped into twenty portfolios as before. For each, the second column shows the number of firms which were delisted from that portfolio over the entire time period. As expected, the smallest size portfolios have the highest number of delistings. This is not, however, evidence that the corrected return varies across size portfolios since the frequency of delisting is not directly relevant. Column three gives the value of  $F$  for each portfolio, and we see that  $F$  is fairly constant across portfolios. There is significant variability for the portfolios of larger firms because of the low number of observations, but nothing to suggest a systematic pattern. Column four shows the mean value of  $R_F$  for each of the portfolios, and again, we see no systematic pattern. For the last factor, we have a much smaller number of observations since a stock must have both pre-delisting and post-delisting bid-ask spread data to be in the sample. We give the number of firms separately in column five. The last column shows the mean of the third factor, and we see that it is essentially constant across portfolios.

In sum, Table 6 shows no evidence that any of the three factors vary by size, so a single corrected return appears appropriate for all delisted firms.

## 5 Conclusion

In this paper, we document that many returns in CRSP's database are missing for firms which are delisted from Nasdaq for performance reasons, and that firms delisted for reasons other than poor performance have a very low frequency of missing data. We collect data on 63% of the observations where post-delisting returns are missing and show that they

are significantly negative on average, indicating that omitting these returns introduces a significant bias. This delisting bias is 4.7 times larger than the delisting bias in NYSE and AMEX data documented by Shumway (1997). We also document that the relative bid-ask spreads of firms delisted for performance reasons increases dramatically, which further reduces the wealth of investors holding these stocks. From alternate data sources, we estimate a corrected average delisting return of  $-55\%$  for firms which are delisted for performance reasons. Researchers can use this figure wherever CRSP shows a missing return for firms delisted from Nasdaq for performance reasons to compensate for the delisting bias in the unmodified database. It is also a reasonable estimate of the return to temporarily delisted stocks which do not have delisting information in the CRSP data.

The delisting bias in Nasdaq stocks is critical to the evidence of a size effect in Nasdaq stocks. Previous evidence that smaller Nasdaq stocks earn higher returns essentially disappears when the data is corrected for missing delisting returns. We also find that the apparent size effect (when the data is uncorrected for the delisting bias) in Nasdaq stocks has not diminished over time, and that it does not survive correction for the delisting bias in the earlier as well as the later part of the sample. Consequently, there is no evidence that there was ever a size effect among Nasdaq stocks. Banz (1981) found the size effect to be most pronounced among the smallest firms. Therefore, finding no size effect among Nasdaq stocks which are the smallest in the marketplace is particularly strong evidence against the economic importance of the size effect and supports the contention of Lo and MacKinlay (1990) and Black (1993) that the size effect is due to data snooping rather than economic fundamentals.

The size of the delisting bias and its reversal of previous inferences indicates that the delisting bias is an important consideration in studies using Nasdaq data. Studies that sort stocks into portfolios based on size, distress, or similar characteristics are particularly susceptible to the bias and it is, therefore, particularly important that the returns used be corrected for the bias.

Table 1  
Delisting Returns in CRSP's Nasdaq Data

Delistings are categorized according to the reason given by CRSP for the delisting. Shown are the number of delistings that fall in each category and the percentage of returns in each category for which the delisting return (DRET) is missing. Data are from CRSP's 1995 daily Nasdaq file. Sample period is 1972 through 1995.

Reason for Delisting	CRSP Code	Number	% of all Perf. Delists	% Missing DRET
Merger	200-240	2463		.9
Exchange	300-390	292		1.0
Liquidation	400	138		71.0

Average	220	3931	5.6

Table 3  
New Delisting Returns

Price data for stocks whose delisting returns are missing from CRSP's Nasdaq data base were collected from the *Pink Sheets*, Bloomberg, and the *Directory of Obsolete Securities*. This table summarizes the delisting returns calculated using that price data. The first column indicates the CRSP code for the delisting, the second indicates the number of stocks in that group that have missing delisting returns, the third gives the number of stocks for which we were able to identify a new delisting return, the fourth and fifth columns show the mean and median of the new delisting returns, and the sixth column gives the t-statistic for the null hypothesis that the mean new delisting return is equal to zero. Sample period is 1977 through June of 1994. The number of delistings is different than in Table 2 because of the difference in sample periods.

CRSP Code	Num.	DRET	Median	Mean	T-Stat
500	550	391	-18.8	-20.8	-9.99
560	914	606	-37.5	-28.9	-11.28

Table 4  
Average Monthly Returns for 20 Size Portfolios

All Nasdaq stocks are assigned to one of twenty portfolios each year based on their market capitalization at the end of the previous year. Returns are calculated as equal-weighted averages of monthly returns for all the stocks in the portfolio. Column 2 gives the mean market capitalization of the stocks in the portfolio, and column 3 shows the frequency with which stocks are delisted. Column 4 ("CRSP") shows the mean return for the portfolio calculated with CRSP data alone, column 5 ("Corr.") shows mean returns using a value of  $-55\%$  for all missing delisting and temporary delisting returns. The last 2 columns report t-statistics for a test of whether the portfolio's average return is equal to the average return of the entire sample. F-statistics and p-values are reported for a test of whether all portfolio average returns are equal. Data are from CRSP's 1995 daily Nasdaq file. Sample period is 1972 through 1995.

Size Portf.	Mean Size (\$mill)	Delisting Freq. (%/mo.)	Mean Return (%)		T-stat $H_0: \bar{R}_i = \bar{R}$		
			CRSP	Corr.	CRSP	Corr.

Table 5  
Sensitivity Analysis of Average Monthly Returns for 20 Size Portfolios

The analysis of Table 4 is repeated with modifications. All Nasdaq stocks are assigned to one of twenty portfolios each year based on their market capitalization. Columns 2 and 3 show equal-weighted average monthly returns for the subperiod 1973-1985, and columns 4 and 5 show mean returns for 1986-1995. "CRSP" indicates that missing delisting returns are not corrected, and "Corr." indicates that a return of  $-55\%$  is used for all missing permanent and temporary delistings. Column 6 shows mean returns when only delisting returns (DRETs) are corrected and temporary delisting returns are not. Columns 7 and 8 use corrected delisting returns of  $-66\%$  and  $-43\%$  respectively. Columns 9 and 10 use annual returns (expressed as compounded monthly returns for comparison) rather than monthly returns. F-statistics and p-values are reported for the test of whether all portfolio average returns are equal. The data are from CRSP's 1995 daily Nasdaq file, 1972-1995 unless noted otherwise.

Size Port.	1973-1985		1986-1995		DRET Only	$R_{Corr} =$ -66%	$R_{Corr} =$ -43%	Annual Returns	
	CRSP	Corr.	CRSP	Corr.	Corr.	Corr.	Corr.	CRSP	Corr.

Table 6  
Components of the Corrected Delisting Return as a Function of Size

All Nasdaq stocks are assigned to one of twenty portfolios each year based on their market capitalization at the end of the previous year. Columns 2 and 5 report the number of performance delistings (temporary as well as permanent) for each portfolio.  $F$  is the fraction of delistings for which we were able to identify delisting returns.  $R_F$  is the delisting return calculated using post-delisting prices. Only Nasdaq stocks for which bid-ask data is available before and after delisting are included in the last two columns.  $(1 - \frac{S_1}{2}) / (1 - \frac{S_0}{2})$  is a measure of the change in the relative bid-ask spread around delisting. The sample period is January 1977 through June 1994. The number of observations is less than in Table 3 because data on firm size is not available for some stocks.

Size	Portf.	Num.	F	Mean $R_F$ (%)	Bid-Ask Spread	
					Num.	Mean $\frac{1 - \frac{S_0}{2}}{1 - \frac{S_1}{2}}$
smallest	1	883	.60	-24.3	54	.751
	2	495	.67	-23.8	36	.790
