The provenance of water and organic compounds on Earth and other terrestrial planets has been discussed for a long time without reaching a consensus. One of the main means to distinguish between different scenarios is by determining the deuterium-to-hydrogen (D/H) ratios in the reservoirs for comets and Earth’s oceans.

Here, we report the direct in situ measurement of the D/H ratio in the Jupiter family comet 67P/Churyumov-Gerasimenko by the ROSINA mass spectrometer aboard the European Space Agency’s Rosetta spacecraft, which is found to be (5.3 ± 0.7) × 10⁻⁴—that is, approximately three times the terrestrial value. Previous cometary measurements and our new finding suggest a wide range of D/H ratios in the water within Jupiter family objects and preclude the idea that this reservoir is solely composed of Earth ocean–like water.

The delivery of water and organic compounds to Earth and other terrestrial planets is still under debate (1–4). Existing scenarios range from negligible (1, 2) to substantial (3, 4) cometary contributions to terrestrial water. Hence, the comparison of the deuterium-to-hydrogen ratio (D/H) in water between the different populations of comets and Earth’s oceans is crucial if one wants to distinguish among these scenarios. Previous D/H measurements have been made for a dozen comets from the Oort cloud and the Jupiter family [for example, (5) and references therein]. So far, only one measurement has been made in situ: in the coma of the Oort-cloud comet 1P/Halley, via the mass spectrometers present aboard the European Space Agency (ESA) Giotto spacecraft, and based on an assumption made on the oxygen isotopic composition (6, 7). Here, we report the direct in situ measurement of the D/H ratio in the Jupiter family comet (JFC) 67P/Churyumov-Gerasimenko.

The mass spectrometer ROSINA-DFMS (Rosetta Orbiter Sensor for Ion and Neutral Analysis, Double Focusing Mass Spectrometer) on the European cometary space mission Rosetta is designed to measure isotopic ratios (8). Its mass resolution and high dynamic range enable it to detect very rare species such as HD¹⁸O relative to the most abundant isotope H₂¹⁸O (9). ROSINA has the capability to measure all isotopic ratios in water independently (D/H, H²¹⁸O/H₂¹⁸O, and H₂O/H₁₈O), and the D/H ratio can be deduced from two different species, namely HD²⁰O/H₂¹⁸O and HD¹⁸O/H₁₈O.

Rosetta has a neutral gaseous background due to spacecraft outgassing. The permanent particle density in the close vicinity of the spacecraft far away from the comet is ~10⁻⁹ cm⁻³, consisting mostly of water but also of organic material, fragments of hydrasine, and vacuum grease (fluorine). Even after 10 years in space and after hibernation, the background from Rosetta can be measured and characterized with ROSINA (10). The D/H ratio in water outgassed from the Rosetta spacecraft is compatible with the terrestrial value of 1.5 × 10⁻⁴, as expected (9), and did not vary with time of degrading, indicating negligible isotope fractionation. These observations demonstrate the capability of DFMS and of the analysis method. On 1 August 2014, Rosetta was within 1000 km from comet 67P/Churyumov-Gerasimenko at 3.6 astronomical units (AU) from the Sun, and the coma was still hidden beneath the spacecraft background for in situ measurements. However, a few days later it approached the comet to within 100 km. The factor of 100 larger densities at this distance surpassed the spacecraft background by more than a factor of 2; the difference between background (26 May) and coma (22 August) at mass 19 dalton is evident (Fig. 1). There are four peaks on mass 19 dalton: fluorne, which is due to background (vacuum grease) from the spacecraft (10); H₂¹⁸O, a fragment from H₂¹⁸O due to electron impact ionization in the instrument and a minor contribution from photodissociation of water in the coma; H₂¹⁸O and HD¹⁸O. All mass peaks have the same shape. H₂¹⁸O is hidden in the shoulder of

Fig. 1. Typical mass/charge 19 daltons/e spectra from DFMS data are shown for 26 May 2014, when the spacecraft was at 800,000 km from the nucleus, and for 22 August, with the spacecraft at 60 km from the nucleus. The integration time was 20 s. The number of ions detected are plotted as a function of m/z. The peak fits for 26 August are also shown for fluorne (F), H₂¹⁸O, H₂O, and HDO, using the same peak width for all species.

†Deceased.
The period of 12 hours corresponds almost to a comet rotation (12.4-hour period). The times given are those for the measurement of m/z 18 (H₂¹⁷O), m/z 19 (HDO and H₂¹⁸O), and 20 (H₂³⁰O) are measured 30 s and 1 min later, respectively. The error bars represent statistical errors from the low count rates and errors from the fit. Errors due to background and due to uncertainties in the detector gain, which are of a systematic nature, are only considered for the mean ratios given in the text.

The much larger peak of HDO. Because the positions of the masses are known, the only fit parameters remaining are the amplitudes. In this way, H₂¹⁷O can clearly be separated from HD¹⁶O.

Before 5 August, all species had a very similar intensity. However, on 8 August the intensity of HD¹⁶O was more than double the height of the HDO peak, whereas fluorene stayed constant. This can only be attributed to a much higher D/H ratio in water. By 22 August, the background was almost negligible because the spacecraft was now within 50 km from the nucleus. However, the signal on mass 21 (HD²⁰O) was still very low. Water peaks on mass 18 and 19 dalton were therefore analyzed by using more than 50 spectra taken between 8 August and 5 September, leading to a derivation of D/H from HD²⁰O/H₂¹⁶O ratio (analysis is described in (9)). Uncertainties of the measurements are carefully estimated by error propagation, taking into account statistical uncertainties in the measured signal and uncertainties originating from calibration, background subtraction, and fitting methods. The biggest contribution is probably the uncertainty for the background because Rosetta is now permanently in the cometary coma, and background corrections have to be done with data from before August 2014. Analysis of the spacecraft background over the 10 years of the cruise phase, however, has shown that for a stable spacecraft attitude, the background remains stable over very long times outside of reaction wheel offloads (10). The value derived from our analysis for D/H is (5.3 ± 0.7) × 10⁻⁸ (2σ error, where σ is the SD as described above).

By deriving HDO relative to H₂¹⁶O, we also found the T²¹⁸O/T¹⁶O ratio. Additionally, the ratio of T²¹⁸O/T¹⁶O follows from the analysis of mass-to-charge ratio (m/z = 20 daltons), which contains two well-separated peaks: H₂¹⁸O (20.01484 daltons) and H²¹⁰O (20.0062 daltons) (Fig. 2). H²¹⁰O is almost entirely due to spacecraft background. The results for the oxygen isotopic ratios in cometary water are compatible with solar system values, with T²¹⁸O/T¹⁶O = (3.7 ± 0.9) × 10⁻⁴ and T²¹⁸O/T¹⁶O = (1.8 ± 0.2) × 10⁻³. Although from the figure one might see a small modulation for the ratios as a function of rotation of the comet, statistics are too poor to come to a conclusion. Once the comet activity increases, it should be feasible to narrow down the values for the heavy isotopes of water.

The D/H ratio shows dramatic variations among solar system reservoirs of water (Fig. 3). The protosolar nebula (PSN) D/H value is estimated to be (2.1 ± 0.5) × 10⁻³ based on measurements of H₂ in the atmosphere of Jupiter (11) and (³He+D)/H in the solar photosphere (12). This value is close to interstellar D/H ratios of H₂ around 2.0 × 10⁻³ to 2.3 × 10⁻³ (13). In contrast, most solar system objects are enriched in deuterium (Fig. 3), with an enrichment factor defined as the ratio (D/H)object/(D/H)PSN averaging 6 for the inner solar system (including Earth, the Moon, and volatile-rich primitive meteorites such as carbonaceous chondrites). Comets analyzed so far, mostly long-period ones, display higher f values, typically in the 10 to 20 range. The cause of the deuterium enrichment in solar system bodies is usually attributed to water-ice rich in deuterium infalling from the presolar cloud onto the nebula disk (3). Therefore, because comets may have accreted ice with various chemical histories (14), several mechanisms have been proposed that would induce a deuterium fractionation in the early PSN. Because a part of the ice accreted by comets could have vaporized and recondensed within the PSN, an isotopic exchange could have occurred between the initially deuterium-rich water and molecular hydrogen in the warm regions of the disk (15). At low temperatures, this reaction favors the concentration of deuterium in HDO, but the extremely slow kinetics tend to inhibit the reaction. In these models, isotopic exchange occurs as long as H₂O does not crystallize, implying that the observed D/H ratios should be representative of the local values where and when the building blocks of the host objects condensed (16). Alternatively, a part of the ice accreted by comets could have remained pristine (14). Under these circumstances, gas-grain reactions could have induced deuterium fractionation in the cold outer part of the PSN (17, 18). Regardless of the fractionation mechanism, all of these models are consistent with a deuterium enrichment profile following a radial increase throughout the PSN from low values close to the Sun to high values in the outer part of the disk (16–18).

Most D/H ratio measurements in water in comets come from long-period comets, presumably originating from the Oort cloud (Oort Cloud Comets (OCCs)). Population of this cometary reservoir is attributed to the scattering of icy bodies originally located in the Uranus-Neptune formation region between ~10 and 15 AU in the PSN (19), although a nonsolar, external origin for a large fraction of OCCs has recently been proposed (20). In contrast, JFCs are expected to have formed in the Kuiper Belt region beyond Neptune (21). D/H ratios of OCCs, analyzed either in situ by means of mass spectrometry in the case of comet Halley (6, 7) or spectroscopy (5), show a range varying from ~1.3 to 2.9 times the terrestrial value (f ~ 9.8 to 21.9) (Fig. 3). In addition, the D/H ratio was found to be similar to the comet Halley in situ measurements in the water plume of Saturn’s satellite Enceladus (22). These values support the predicted D/H radial increase with distance from the Sun and the origin of OCCs from a common, localized region of the disk (16–18).

Recent D/H measurements in water in the two JFCs analyzed so far—namely, (1.61 ± 0.24) × 10⁻⁴ (f ~ 7.8) for 103P/Hartley 2 (23) and an upper limit of 2.0 × 10⁻⁴ (f < 9.5) for 46P/Honda-Mrkos-Pajdušáková (5)—contradict this view. The hydrogen isotope composition of 103P/Hartley 2 is closer to the terrestrial value than the OCCs average, reviving the possibility of a cometary, rather than asteroidal, origin for the oceans. These data lead to two possible conclusions: Either JFCs originate from the Kuiper Belt and the chemical models developed so far (16–18) are not representative, or these comets formed over a wide range of heliocentric distances in the outer part of the PSN. With regard to the first possibility, a recent chemical model leading to a non-monotonic f profile throughout the PSN (24) matches these observations if the JFCs were formed in the Kuiper Belt (21). In contrast with previous PSN models evolving as closed systems, this model assumes that the disk continues to be fed by material infalling from the presolar cloud. Alternatively, it has been proposed that JFCs and OCCs could originate from the same extended outer region of the PSN (25), so that 103P/Hartley 2 and 46P/Honda-Mrkos-Pajdušáková (46P/HMP) may simply have formed in the inner part of this common reservoir. In this case, the range of D/H ratios measured in JFCs should be similar to the one found in OCCs, as suggested by observations.

The new D/H value of (5.3 ± 0.7) × 10⁻⁸ (f ~ 25.25) from comet 67P/Churyumov-Gerasimenko is not consistent with previous JFC data and is even higher than values characteristic of OCCs (~30
to 120% higher than that of comet Halley). In contrast to previous JFC measurements, this estimate matches models that predict a monotonic radial increase of the enrichment profile (16–18). From the ROSINA measurements on comet 67P/Churyumov-Gerasimenko, we conclude that the D/H values of JFCs may be highly heterogeneous, possibly reflecting the diverse origins of JFCs. If this is the case, then the new measurement supports models advocating an asteroidal (carbonaceous chondrite–like) rather than cometary origin for the oceans, and by extension for the terrestrial atmosphere (1, 2).
